```
# Get all values
values = list(stock_data.values())  # ["AAPL", 145.86, 28.35, "Technology"]

# Get key-value pairs as tuples
items = list(stock_data.items())  # [("symbol", "AAPL"), ("price", 145.86), ...]

# Check if a key exists
has_volume = "volume" in stock_data  # False
```

These methods provide flexible ways to work with dictionary data, which is essential when building complex trading systems that need to access and analyze information in different ways.

Nested Dictionaries: Complex Financial Data Structures

Dictionaries can contain other dictionaries, allowing you to represent complex, hierarchical data:

```
# A portfolio with detailed position information
portfolio = {
    "AAPL": {
        "shares": 100,
        "average_price": 142.32,
        "sector": "Technology",
        "stop_loss": 135.00
    },
    "JNJ": {
        "shares": 50,
        "average_price": 165.78,
        "sector": "Healthcare",
        "stop_loss": 160.00
    }
}

# Access nested information
apple_shares = portfolio["AAPL"]["shares"]  # 100
jnj_sector = portfolio["JNJ"]["sector"]  # "Healthcare"
```
