

This would display:

Stock: AAPL

Current price: 142.58

Position value: 14258.0

You can format your output for better readability:

```
1. position_value = current_price * shares_owned
2.
3. # Format as currency
4. print(f"Position value: ${position_value:,.2f}")
```

This would display:

Position value: \$14,258.00

The f"..." syntax creates an f-string (formatted string), allowing you to embed variables and expressions directly in your text.

The input() Function: Getting User Information

The input() function collects information from the user:

```
1. symbol = input("Enter stock symbol: ")
2. price = float(input("Enter current price: "))
3. shares = int(input("Enter number of shares: "))
4.
5. position_value = price * shares
6. print(f"Your {symbol} position is worth ${position_value:,.2f}")
```

This program would:

1.
Ask the user for a stock symbol, price, and number of shares
2.
Calculate the position value
3.
Display the result formatted as currency

Note that input() always returns a string, so we use float() and int() to convert the input to the appropriate data type for numerical calculations.
