Next, Exhibit 2.5 uses survival data to calculate the distribution for the actual age of death for sixty-five-year-olds. This is the probability that each age will serve as your last. The exhibit helps highlight the uncertainties around longevity risk. For instance, 10 percent of males will have died by 74.3, the median age is 88.9, and 10 percent are still alive by 98.4. The corresponding numbers for females are 75.8, 90.5, and 100.1. These wide ranges can make planning difficult.

Exhibit 2.5

Distribution for Age of Death for 65-Year-Olds
